Abstract

Let $X$ denote the feature and $Y$ the target. We consider domain adaptation under three possible scenarios: (1) the marginal $P_Y$ changes, while the conditional $P_{X|Y}$ stays the same (target shift), (2) the marginal $P_Y$ is fixed, while the conditional $P_{X|Y}$ changes with certain constraints (conditional shift), and (3) the marginal $P_Y$ changes, and the conditional $P_{X|Y}$ changes with constraints (generalized target shift). Using background knowledge, causal interpretations allow us to determine the correct situation for a problem at hand. We exploit importance reweighting or sample transformation to find the learning machine that works well on test data, and propose to estimate the weights or transformations by reweighting or transforming training data to reproduce the covariate distribution on the test domain. Thanks to kernel embedding of conditional as well as marginal distributions, the proposed approaches avoid distribution estimation, and are applicable for high-dimensional problems. Numerical evaluations on synthetic and real-world data sets demonstrate the effectiveness of the proposed framework.

1. Introduction

The goal of supervised learning is to infer a function $f$ from a training set $D^{tr} = \{(x_1^{tr}, y_1^{tr}), ..., (x_m^{tr}, y_m^{tr})\} \subseteq X \times Y$, where $X$ and $Y$ denote the domains of predictors $X$ and target $Y$, respectively. The estimated $f$ is expected to generalize well on the test set $D^{te} = \{(x_1^{te}, y_1^{te}), ..., (x_n^{te}, y_n^{te})\} \subseteq X \times Y$, where $y_i^{te}$ are unknown. Traditionally, the training set and test set are assumed to follow the same distribution. However, in many real world problems, the training data and test data have different distributions, i.e., $P_{XY}^{tr} \neq P_{XY}^{te}$, and the goal is to find a learning machine that performs well on the test domain. This problem is known as domain adaptation in machine learning.

If the data distribution changes arbitrarily, training data would be of no use to make predictions on the test domain. To perform domain adaptation successfully, relevant knowledge in the training (or source) domain should be transferred to the test (or target) domain. For instance, the situation where $P_{XY}^{tr}$ and $P_{XY}^{te}$ only differ in the marginal distribution of the covariate (i.e., $P_X^{tr} \neq P_X^{te}$, while $P_{Y|X}^{tr} = P_{Y|X}^{te}$) is termed covariate shift (Shimodaira, 2000; Sugiyama et al., 2008; Huang et al., 2007) or sample selection bias (Zadrozny, 2004), and has been well studied. For surveys on domain adaptation for classification, see, e.g., Jiang (2008); Pan & Yang (2010); Candela et al. (2009).

In particular, we address the situation where both the marginal distribution $P_X$ and the conditional distribution $P_{Y|X}$ may change across the domains. Clearly, we need to make certain assumptions for the training domain to be adaptable to the test domain. We first consider the case where $P_{X|Y}$ is the same on both domains. As a consequence of Bayes’ rule, the changes in $P_X$ and $P_{Y|X}$ are caused by the change in $P_Y$, the marginal distribution of the target variable. We term this situation Target Shift (TarS) which is frequently encountered in practice; for instance, it is known as choice-based or endogenous stratified sampling (Manski & Lerman, 1977) in econometrics, and is sometimes called prior probability shift (Storkey, 2009).

We further discuss the situation where $P_Y$ remains the same, while $P_{X|Y}$ changes, as termed conditional shift (ConS). Estimation of $P_{XY}^{te}$ under ConS is in general ill-posed; we consider a rather practical yet identifiable case where $P_{X|Y}$ changes under location-scale...
(LS) transformations on $X$. We show how to transform the training points to mimic the distribution of test data and facilitate learning on the test domain. Finally, the situation in which both $P_Y$ and $P_{X|Y}$ change across domains is termed \textit{generalized target shift} (GeTarS); we focus on LS-GeTarS, i.e., GeTarS with $P_{X|Y}$ changes under LS transformations, and propose practical methods to estimate both changes, making domain adaptation possible.

It has been demonstrated that causal information can be derived from changes in data distributions (Tian & Pearl, 2001); on the other hand, knowledge of the data generating process, or causal knowledge, would imply how the data distribution changes across domains and help in domain adaptation. Schölkopf et al. (2012) demonstrated that a number of learning tasks, especially semi-supervised learning, can be understood from the causal point of view. The problems studied here, TarS, ConS, and GeTarS, have clear causal interpretations. Throughout the paper, we assume that $Y$ is a cause of $X$. If we further know that $X$ depends on the domain (or selection variable) only via $Y$, we have the TarS situation: the marginal distribution of the cause, $P_Y$, describes the process which generates $Y$ in the domain, and $P_{X|Y}$ describes the data generating mechanism for $X$ from the cause $Y$, which is independent of the domain. According to Woodward (2003), the invariance of $P_{X|Y}$ w.r.t. the change in $P_Y$ is one of the features of the causal system $Y \rightarrow X$. Consider the clinical diagnosis as an example. The disease is naturally considered as the cause of symptoms; moreover, the marginal distribution of the disease could change across different regions, but the conditional distribution of the symptoms given the disease is expected to be invariant. Furthermore, if both $Y$ and the domain are causes of $X$ while $Y$ is independent of the domain, we have the ConS situation. More generally, the situation where $Y$ is a cause of $X$ and both $P_Y$ and $P_{X|Y}$ depend on the domain corresponds to GeTarS.

In the classification scenario, target shift was referred to the class imbalance problem by Japkowicz & Stephen (2002). To solve it, sometimes it is assumed that $P^t_Y$ is known \textit{a priori} (Lin et al., 2002), or that some knowledge about the change in $P_Y$ is known (Yu & Zhou, 2008). However, this is usually not the case in practice. Chan & Ng (2005) proposed to estimate $P^t_Y$ with an EM algorithm. Unfortunately, this approach has to estimate $P^t_{X|Y}$, which is a difficult task if the dimensionality of $X$ is high; moreover, it does not apply to regression problems. In fact, lack of information on $P^t_{X|Y}$ causes the main difficulty in domain adaptation under TarS.

In this paper we provide practical approaches for domain adaptation under TarS, LS-ConS, and LS-GeTarS, by sample importance reweighting or sample transformation. The approach for TarS also applies to regression. Kernel embedding of both conditional and marginal distributions provides a convenient tool to estimate the importance weights or the sample transformations. With it, we are able to avoid estimating any distribution explicitly, and the proposed approaches apply to high-dimensional problems without any difficulty. We note that kernel distribution embedding has been used to correct for covariate shift in Huang et al. (2007); Gretton et al. (2008), but the studied problems are inherently different: they used the kernel mean matching to estimate the ratio $P_{XY}^t/P_{XY}$, avoiding estimating $P_{X|Y}^t$ and $P_{X|Y}$ explicitly from data; in our problems we are interested in how $P_{X|Y}^t$ is different from $P_{X|Y}$ (for TarS and GeTarS) or how $P_{X|Y}^t$ changes to $P_{X|Y}$ (for ConS and GeTarS), but there are no data points available to estimate $P_{X|Y}^t$ or $P_{X|Y}$, making the problems much more difficult to solve.

2. Distribution Shift Correction

In this section, we outline two scenarios for distribution shift correction, namely, \textit{importance reweighting} and \textit{sample transformation}.

Importance Reweighting We aim to find the function $f(x)$ that minimizes the expected loss on test data. Assume the support of $P_{XY}$ is contained by that of $P_{XY}^t$. The expected loss is $[P_{XY}^t, \theta, l(x, y; \theta)] = \mathbb{E}_{(x, y) \sim P_{XY}^t}[l(x, y; \theta)] = \int P_{XY}^t \cdot \gamma_x l(x, y; \theta) dx dy = \mathbb{E}_{(x, y) \sim P_{XY}^t} [\beta^*(y) \cdot \gamma^*(x, y) \cdot l(x, y; \theta)]$, where $\theta$ denotes the parameters in the loss function $l(x, y; \theta)$, $\beta^*(y) \equiv P_{XY}/P_{XY}^t$, and $\gamma^*(x, y) \equiv P_{XY}^t/P_{XY}$. Here we factorize $P_{XY}$ as $P_Y P_{X|Y}$ instead of $P_X P_{Y|X}$ because it provides a more convenient way to handle the change in $P_{XY}$, according to our assumptions given later. In practice, we minimize the empirical error,

$$R = \frac{1}{m} \sum_{i=1}^{m} \beta^*(y_i^t) \gamma^* (x_i^t, y_i^t) l(x_i^t, y_i^t; \theta),$$

(1)

to find the supervised learning machine which is expected to work well on test data, if $\beta^*(y_i^t) \gamma^* (x_i^t, y_i^t)$ are given. Readers who are interested in how to reduce the variance of the empirical expected loss may refer to, e.g., Shimodaira (2000); Robert & Casella (2004).

Sample Transformation and Reweighting Sample reweighting only applies when the sup of $P_{XY}^t$
Domain Adaptation under Target and Conditional Shift

is contained in that of \( P_{X|Y}^{te} \): even under this condition, it is usually very difficult to estimate \( \gamma^*(x, y) \) without prior knowledge on how \( P_{X|Y} \) changes. Therefore, in the case where both \( P_Y \) and \( P_{X|Y} \) change, the application of the sample reweighting scheme is rather limited. Instead, if we can find the transformation from \( P_{X|Y}^{tr} \) to \( P_{X|Y}^{te} \), we can estimate the conditional distribution \( P_{X|Y}^{new} = T(X^{tr}, Y^{tr}) \) for \( X^{new} \) and \( Y^{new} \). Therefore, in this problem, we have to estimate \( \mu_1(x) \gamma_1(x) \gamma_2(y) \) identically to \( \mu_2(x) \gamma_2(y) \), where \( \gamma_2(y) = 1 \), and propose a practical method to estimate \( \beta^r(y) \) as well as \( P_Y^{te} \) based on kernel embedding of conditional and marginal distributions.

### 3.2. A Kernel Mean Matching Approach

Instead, we solve this problem by making use of the kernel mean embedding of the marginal and conditional distributions; see Table 1 for the notation we use. The kernel mean embedding of \( P_X \) (Smola et al., 2007; Gretton et al., 2007) is a point in the Reproducing Kernel Hilbert Space (RKHS) given by \( \mu[P_X] = \mathbb{E}_{X \sim P_X} \psi(X) \), and its empirical estimate is \( \hat{\mu}[P_X] = \frac{1}{m} \sum_{i=1}^m \psi(x_i) \). The embedding of the conditional distribution has been studied by Song et al. (2009; 2010). The embedding of \( P_{X|Y} \) can be considered as an operator mapping from \( \mathcal{G} \) to \( \mathcal{F} \), defined as \( \mathcal{U}[P_{X|Y}] = C_{XY} C_{Y|X}^{-1} \), where \( C_{XY} \) and \( C_{Y|X} \) denote the (uncentered) cross-covariance and covariance operators, respectively (Fukumizu et al., 2004). Furthermore, we have \( \mu[P_X] = \mathcal{U}[P_{X|Y}] \mu[P_Y] \).

We make the following assumptions on \( P_Y^{te} \) and \( P_{X|Y}^{tr} \):

\( A_2^{TarS} \): The support of \( P_Y^{te} \) is contained in the support of \( P_Y^{tr} \) (i.e., roughly speaking, the training set is richer than the test set).

\( A_3^{TarS} \): There exists only one possible distribution of \( Y \) that, together with \( P_{X|Y}^{tr} \), leads to \( P_Y^{tr} \).

Imagine that we can draw a biased sample from the training data; here the selection variable depends only on \( Y \), i.e., it is independent of \( X \) given \( Y \). Denote by \( P_{X|Y}^{new}(\cdot) \) the distribution on this sample. Note that \( P_{X|Y}^{new} = P_{X|Y}^{te} \). Thus, we can make \( P_{X|Y}^{new} \) identical to \( P_Y^{tr} \) by adjusting \( P_{X|Y}^{te} \).

Let \( \beta(y) \) be the ratio of the \( P_{X|Y}^{new} \) to \( P_Y^{tr} \), i.e., \( P_{X|Y}^{te} = \beta(y) \cdot P_Y^{tr} \). To make \( P_{X|Y}^{new} \) identical to \( P_Y^{tr} \), we can adjust \( \beta(y) \) to minimize \( D(P_{X|Y}^{te}, P_{X|Y}^{new}) = D(P_{X|Y}^{te}, \int P_Y^{tr} \beta(y) P_Y^{tr}(dy)) \), where \( D \) measures the difference between two distributions; it can be the mean square error or the Kullback-Leibler distance.

To solve this problem, we have to estimate \( P_Y^{te} \), \( P_{X|Y}^{tr} \), and \( P_Y^{tr} \) from the training set, and moreover, the integral makes optimization very difficult.

### 3.1. Assumptions

We first consider Target Shift (TarS):

\( A_1^{TarS} \): \( P_{X|Y}^{te} = P_{X|Y}^{tr} \) and \( P_Y^{te} \neq P_Y^{tr} \).

That is, the difference between \( P_{X|Y}^{te} \) and \( P_{X|Y}^{tr} \) is caused by a shift in target distribution \( P_Y \).

Fig. 1 shows a causal interpretation of TarS. For classification problems, it is possible to estimate \( P_Y^{te} \) in an iterative way by maximizing the likelihood on \( x^{te} \), for instance, with the EM algorithm (Chan & Ng, 2005); however, such approaches involve estimation of \( P_{X|Y} \) explicitly, which is difficult for high-dimensional problems. They are also not practical for regression.

We make the following assumptions on \( P_Y^{te} \) and \( P_{X|Y}^{tr} \):

\( A_4^{TarS} \): Product kernel \( kl \) on \( X \times Y \) is characteristic.

For characteristic kernels, the kernel mean map \( \mu \) from the space of the distribution to the RKHS is injective, meaning that all information of the distribution is preserved (Fukumizu et al., 2008; Sriperumbudur et al., 2011). In this paper we use the Gaussian kernel, i.e., \( k(x_i, x_j) = \exp(-\frac{||x_i-x_j||^2}{2\sigma^2}) \), where \( \sigma \) is the kernel width. Note that under assumptions \( A_3^{TarS} \) and \( A_4^{TarS} \), the embedding of \( \mathcal{U}[P_{X|Y}] \), which is a mapping from \( \mathcal{G} \) to \( \mathcal{F} \), the pre-image of \( \mu[P_Y^{te}] \) is unique.
The kernel mean embedding of $P_{Y_{new}}$ is

$$
\mu[P_{Y_{new}}] = \mathbb{E}_{Y \sim P_{Y_{new}}} [\phi(Y)] = \mathbb{E}_{Y \sim P_{Y_{new}}} [\beta(y) \phi(Y)].
$$

(3)

The embedding of $P_{X_{new}}$ is then given by $\mu[P_{X_{new}}] = \mathcal{U}[P_{X|Y}^{|}] \mu[P_{Y_{new}}]$. Consequently, in the population version, we can find $\beta(y)$ by minimizing the maximum mean discrepancy:

$$
||\mu[P_{Y_{new}}^{|}] - \mu[P_{X_{new}}^{|}]|| = ||\mathcal{U}[P_{X|Y}^{|}] \mu[P_{Y_{new}}^{|}] - \mu[P_{X_{new}}^{|}]||,
$$

(4)

subject to $\beta(y) \geq 0$ and $\mathcal{U}[P_{Y_{new}}^{\beta}] \beta(y) = 1$, which guarantees that $P_{Y_{new}}^{|\beta} = \beta(y)P_{Y_{new}}^{|}$ is a valid distribution.

**Theorem 1**
Under assumptions $A_{\text{TarS}}^{2}$, $A_{\text{TarS}}^{3}$, and $A_{\text{TarS}}^{4}$, the minimization problem (4) is convex in $\beta$. Further suppose $A_{\text{TarS}}^{4}$ holds. Then the solution to (4) is $\beta(y) = \frac{P_{y_{new}}^{|\beta}(y)}{P_{Y_{new}}^{|\beta}(y)}$.

For a proof see the supplementary material. In practice we use an empirical version. The empirical estimate of $\mathcal{U}[X|Y]$ is $\hat{\mathcal{U}}[X|Y] = \Psi(L + \lambda I)^{-1} \Phi$. Recall that $m$ and $n$ are the sizes of the training and test sets. Denote by $\mathbf{1}_n$ the vector of $1$’s of length $n$, and by $K^c$ the “cross” kernel matrix between $\mathbf{y}^{tr}$ and $\mathbf{y}^{tr}$, i.e., $K^c = \langle \psi(x_i), \psi(x_j) \rangle$. Let $\beta$ stand for $\beta(\mathbf{y}^{tr})$ and $\hat{\beta}$ for $\beta(y_{new})$. The empirical version of the square of (4) is

$$
\frac{1}{m^2} \beta^T \phi(\mathbf{y}^{tr}) \hat{\mathcal{U}}[X|Y] \hat{\mathcal{U}}[X|Y] \phi(\mathbf{y}^{tr}) \beta
$$

$$
- \frac{2}{mn} \mathbf{1}_n \phi(\mathbf{x}^{tr}) \hat{\mathcal{U}}[X|Y] \phi(\mathbf{y}^{tr}) \beta + \text{const}
$$

$$
= \frac{1}{m^2} \beta^T \Omega \hat{\beta} + \frac{2}{mn} \mathbf{1}_n \phi(\mathbf{x}^{tr}) \Omega \beta + \text{const},
$$

(5)

where we use short-hand notation $\Omega \triangleq L(L + \lambda I)^{-1}$. As shown by Huang et al. (2007, Lemma 3), if $\beta_1 \in [0, B]$, i.e., $B$ is the upper bound of $\hat{\beta}$, given that $\hat{\beta}$ has finite mean and non-zero variance, the sample mean $\frac{1}{m} \sum_{i=1}^{m} \beta_i$ converges in distribution to a Gaussian variable with mean $\mathbb{E}_{P_{Y_{new}}^{|\beta}}(\beta(y))$ and standard deviation bounded by $\frac{B}{2 \sqrt{m}}$. As $\mathbb{E}_{P_{Y_{new}}^{|\beta}}(\beta(y)) = 1$, we have the following constrained quadratic programming (QP) problem:

$$
\text{minimize} \quad \frac{1}{2} \beta^T A \beta - \frac{m}{n} M \beta,
$$

s.t. $\beta_i \in [0, B]$, and $\left| \sum_{i=1}^{m} \beta_i - m \right| \leq me,$

where a good choice of $\epsilon$ is $O \left( \frac{B}{\sqrt{vm}} \right)$.

Note that $\beta$ estimated this way is not necessarily a function of $y$: different data points in the training set with the same $y$ value could correspond to different $\beta$ values. We also found that the $\beta$ values estimated by solving the above optimization problem usually change dramatically along with $y$. We can improve the estimation quality of $\beta$ by making use of reparameterization. First consider the case where $Y$ is discrete. Let $C$ be the cardinality of $Y$ and denote by $v_1, ..., v_C$ its possible values. We can define a matrix $R_{\text{d}}$ where $R_{\text{d}}^{i,k}$ is 1 if $y_i = v_k$ and is zero everywhere else. $\beta$ can then be reparameterized as $\beta = R_{\text{d}} \alpha$, where the $C$-dimensional vector $\alpha$ is the new parameter.

We then consider the case where $Y$ is continuous. Usually both distributions $P_{Y_{new}}^{|\beta}$ and $P_{X_{new}}^{|\beta}$ are smooth, and so is $\beta(y)$. Therefore, we would like to enforce the smoothness of $\beta(y)$ w.r.t. $y$. Let $R^{(c)}(y) \triangleq L_{\beta}(L_{\beta} + \lambda_{\beta} I)^{-1}$, where $L_{\beta}$ is a kernel matrix of $y$ with the Gaussian kernel and $\lambda_{\beta}$ is the regularization parameter. Inspired by KRR (Saunders et al., 1998), we parameterize $\beta(y^{tr})$ as $\beta = R^{(c)} \alpha$ with new parameter $\alpha$. One can consider $\beta$ as a smoothed version of $\alpha$.

Finally, we find $\alpha$ (and $\beta$) in both cases by solving:

$$
\text{minimize} \quad \frac{1}{2} \alpha^T R^T A R \alpha - \frac{m}{n} M \alpha,
$$

s.t. $0 \leq [R \alpha]_i \leq B_{\beta}$ and $|\|R \alpha - m\|_1 \leq m \epsilon,$

(6)

where $R$ stands for $R^{(d)}$ or $R^{(c)}$, depending on whether $Y$ is discrete or continuous. In all our experiments, we set $B_{\beta} = 10$ and $\epsilon = \frac{B_{\beta}}{4 \sqrt{m}}$. We then set $\beta^*$ in (1) to the estimated $\beta$ and $\gamma^*(x_i, y_i) \equiv 1$. Minimizing (1) produces the classifier or regression model after correction for TarS.

4. Location-Scale Conditional Shift

---

Note that although $L_{\beta}$ and $L$ are both kernel matrices of $y$, they have different purposes and might have different hyperparameters, so we use different notations.
In practice, $P_{X|Y}^{tr}$ and $P_{X|Y}^{te}$ might differ to some extent. It is certainly not possible to transfer useful knowledge from the training domain to the test domain if $P_{X|Y}$ changes arbitrarily. However, under certain assumptions on the change in $P_{X|Y}$, one could estimate $P_{X|Y}^{te}$ without knowing $Y$ on test data. In section 2, we assume that $P_{X|Y}$ changes across domains and that $P_{X|Y}^{tr} = P_{X|Y}^{te}$. We term this situation Conditional Shift (ConS); Fig 2 gives its causal interpretation. This situation might be less realistic in practice and will not be considered in our experiments; however, it serves as a foundation for a more general situation, GeTarS, which will be studied in Sec. 5. When considering ConS and GeTarS, we focus on classification problems.

### 4.1. Assumptions and Identifiability

In some situations, we can formulate how the conditional distribution changes. For instance, for the same image, features such as intensities and colors are influenced by illumination, viewing angles, etc., which might change across domains. Modeling such a change enables distribution matching between the training domain and test domain, and consequently improves the performance on the test domain. Here we use the approach of transforming data to reproduce the covariate distribution on the test domain; see Sec. 2. Since we can model the transformation from $P_{X|Y}^{tr}$ to $P_{X|Y}^{te}$, we do not need the condition that the support of $P_{X|Y}^{te}$ is contained in that of $P_{X|Y}^{tr}$, making the approach more practical.

We assume that the shape of the distribution of each feature $X_i$, as well as the dependence structure between features, is preserved across domains. More precisely, we assume that given any $y$ value, $P_{X_i|Y}^{te}$ and $P_{X_i|Y}^{tr}$ only differs in the location and scale:

**A ConS:** There exists $w(Y^{tr}) = \text{diag}[w_1(Y^{tr}), ..., w_d(Y^{tr})]$ and $b(Y^{tr}) = [b_1(Y^{tr}), ..., b_d(Y^{tr})]^T$, where $d$ is the dimensionality of $X$, such that the conditional distribution of $X^{new} \triangleq w(Y^{tr})X^{tr} + b(Y^{tr})$ given $Y^{tr}$ is the same as that of $X^{te}$ given $Y^{te}$.

We term this situation location-scale ConS (LS-ConS). In matrix form, the transformed training points

$$x^{new} \triangleq x^{tr} \circ W + B,$$

where the $i$th columns of $W$ and $B$ are $[w_1(y_i), ..., w_d(y_i)]^T$ and $[b_1(y_i), ..., b_d(y_i)]^T$, respectively, are expected to have the same distribution as the test data. Fig. 3 illustrates on how the contours of $P_{X|Y}$ change across domains under LS-ConS.

The following theorem states that $P_{X|Y}^{new}$ is identifiable under some conditions on $P_{X|Y}^{tr}(x|y)$.

**Theorem 2** Let $P_{X|Y}^{new}(x|y)$ be the LS transformed version of $P_{X|Y}^{tr}(x|y)$ with parameters $(w_i, b_i)$ and $P_{X|Y}^{te} = P_{X|Y}^{tr}$. Suppose $A_{ConS}$ holds, i.e., $\forall i, \exists (w_i^*, b_i^*)$ such that

$$P_{X|Y}^{new}(w_i^*, b_i^*) = P_{X|Y}^{te}(y_i|x_i).$$

Further assume

**A$_1^{ConS}$:** Set $\{c_1P_{X|Y}^{new}(w_i, b_i)|y_i = 1\}$ is linearly independent $\forall c_1, c_2 (c_1^2 + c_2^2 \neq 0)$, $w_i$, $b_i$, $\|w_i\|_2^2 + |w_i| \neq 0$, and $b_i, b_i^*$.

If $\exists (w_i, b_i)$ such that $P_{X|Y}^{te} = \sum_i P_{X|Y}^{new}(w_i, b_i)(x|y_i)$, then we have $\forall i, P_{X|Y}^{new}(w_i, b_i)(x|y_i) = P_{X|Y}^{tr}(x|y_i)$.

A necessary condition for $A_1^{ConS}$ is that $P_{X|Y}^{new}(x|y_i)$, $i = 1, ..., C$, are linearly independent after any LS transformations. Roughly speaking, the higher $d$, the less likely for this assumption to be violated.

### 4.2. A Kernel Approach

As in Sec. 3.2, we parameterize $W$ and $B$ as $W = RG$ and $B = RH$, where $G$ and $H$ are the parameters to be estimated, and $R$ is $R^{(c)}$ or $R^{(d)}$, depending on whether $Y$ is discrete or continuous. In this way $W$ and $B$ are guaranteed to be functions of $y$, and the number of parameters is greatly reduced.

Noting the relationship between $X^{new}$ and $X^{tr}$, and using the substitution rule, we have

$$u(P_{X|Y}^{new}) = \mathbb{E}_{X^{new} \sim P_{X|Y}^{new}}[\psi(X^{new}) \circ \phi^T(Y)] \mathbb{E}_{Y \sim P_Y} \phi(Y) \phi^T(Y)$$

$$= \mathbb{E}_{x^{tr}, y \sim P_{XY}}[\psi(x^{new}) \circ \phi^T(y)] \mathbb{E}_{Y \sim P_Y} \phi(Y) \phi^T(Y).$$

The empirical estimate of $u(P_{X|Y}^{new})$ is consequently

$$\hat{u}(P_{X|Y}^{new}) = \frac{1}{m}\psi(x^{new}) \cdot \phi^T(y^{tr}) \cdot \frac{1}{m} \phi(y^{tr}) \phi^T(y^{tr}) + \lambda I \right)^{-1},$$

$$= \hat{\psi}(L + \lambda I)^{-1} \phi^T,$$

(8)
where $\hat{\Psi} = \psi(x^{new})$.

Let $\hat{K}$ be the kernel matrix corresponding to the feature matrix $\hat{\Psi}$, i.e., $\hat{K}_{i,j} = k(x_i^{new}, x_j^{new})$, and $\hat{K}_c$ the cross kernel matrix between $x^{te}$ and $x^{new}$, i.e., $\hat{K}_{i,j} = k(x_i^{te}, x_j^{new})$. We aim to minimize $||\mu[P_{X}^{new}] - \mu[P_{X}^{te}]||^2$, whose empirical version is

$$ J^{ConS} \triangleq \left\| \hat{\mu}[P_{X}^{new}] - \mu[P_{X}^{te}] \right\|^2 = \left\| \hat{U} [P_{X|Y}^{new}] \hat{\mu}[P_{X}^{te}] - \mu[P_{X}^{te}] \right\|^2 $$

$$ = \frac{1}{m^2} \hat{1}_m \phi^T (y^{tr}) \hat{U}^T \left[ P_{X|Y}^{new} \right] \hat{\mu}[P_{X}^{te}] \phi(y^{tr}) 1_m $$

$$ - \frac{2}{mn} \hat{1}_n \psi^T (x^{te}) \hat{U} [P_{X|Y}^{new}] \phi(y^{tr}) 1_m $$

$$ = \frac{1}{m^2} \hat{1}_m \Omega \hat{K} \Omega^T 1_m - \frac{2}{mn} \hat{1}_n \hat{K} \Omega^T \beta $$

(9)

We then estimate $W$ (or $G$) together with $B$ (or $H$) by minimizing $J^{ConS}$. In practice we also regularize (9) to prefer the change in $P_{X|Y}$ to be as little as possible, i.e., to make entries of $W$ close to one and those of $B$ close to zero. This is particularly useful in case assumption $A_{2}^{ConS}$ is violated: we then prefer the smallest change in the conditional, among all possibilities. The regularization term is

$$ J^{reg} = \frac{\lambda_{LS}}{m} \cdot ||W - 1_m 1_n^T||_F^2 + \frac{\lambda_{LS}}{m} \cdot ||B||_F^2 $$

(10)

One can find the derivative of $J^{ConS}$ and $J^{reg}$ w.r.t. $G$ and $H$, and use the scaled conjugate gradient (SCG) to minimize $J^{ConS} + J^{reg}$. After estimating $W$ and $B$, we transform $x^{tr}$ to $x^{new}$ according to (7), and $(x^{new}, y^{tr})$ would have the same distribution as the test data, under assumption $A^{ConS}$. Consequently, the classifier or regressor trained on $(x^{new}, y^{tr})$ is expected to generalize well to the test domain.

5. LS Generalized Target Shift

We then consider a more general situation where both $P_Y$ and $P_{X|Y}$ change, called Generalized Target Shift (GeTarS). Fig. 4 gives the causal model underlying the GeTarS situation.

In this setting, we assume that $P_{X}^{te} \neq P_{X}^{tr}$ and that assumption $A^{ConS}$ holds, i.e., we consider LS-GeTarS, and aim to estimate the importance weights $\beta^{*}(y_i) = \frac{P_{Y}^{te}(y_i)P_{X}^{te}(y_i)}{P_{Y}^{tr}(y_i)P_{X}^{tr}(y_i)}$ and the matrices $W$ and $B$ in (7). They would transform the training data to mimic the distribution of the test data, and the learning machine learned on the reweighted transformed data is expected to work well on the test data. Parameters can be estimated by reweighting and transforming the training data to reproduce $P_{X}^{te}$, i.e., by minimizing $||\mu[P_{X}^{new}] - \mu[P_{X}^{te}]||^2$, where $P_{X}^{new} = \int P_{Y}^{new} P_{X|Y}^{new} dy$, $P_{new} = \beta P_{Y}^{tr}$, and $P_{X|Y}^{new}(x|y_i) = P_{X|Y}^{te}(x|y_i)$. The following theorem provides the identifiability of $P_{X|Y}^{new}$.

**Theorem 3** Suppose $A^{ConS}$ holds. Under assumption $A_{2}^{ConS}$, if there exist $(w_i, b_i)$ such that $P_{X}^{te} = \sum_i P_{X|Y}^{new}(y_i)P_{(w_i, b_i)}(x|y_i)$, then we have $P_{new} = P_{Y}^{te}$, and $\forall i, P_{X|Y}^{new}(x|y_i) = P_{X|Y}^{te}(x|y_i)$.

Combining (3) and (8), we can find the empirical version of $||\mu[P_{X}^{new}] - \mu[P_{X}^{te}]||^2$:

$$ J = \left\| \hat{\mu}[P_{X}^{new}] - \mu[P_{X}^{te}] \right\|^2 $$

$$ = \left\| \hat{U} [P_{X|Y}^{new}] \phi(y^{tr}) - \frac{1}{n} \psi(x^{te}) 1_n \right\|^2 $$

$$ = \frac{1}{m^2} \hat{U}^T \left[ P_{X|Y}^{new} \right] \phi(y^{tr}) \beta - \frac{2}{mn} \hat{1}_n \hat{K} \Omega^T \beta $$

(11)

When minimizing $J$, we would also like the difference between $P_{X|Y}^{te}$ and $P_{X|Y}^{tr}$, as measured by $J^{reg}$ given in (10), to be as little as possible. Combining both constraints, we estimate the involved parameters $\beta$, $W$, and $B$ by minimizing

$$ J^{GeTarS} = J + \lambda_{LS} J^{reg} $$

(12)

Finally, for parameter estimation, we iteratively alternate between the QP to minimize (11) w.r.t $\beta$ and the SCG optimization procedure w.r.t. $\{W, B\}$. Details of the two optimization sub-procedures, see Sections 3 and 4, respectively. After estimating the parameters, we train the learning machine by minimizing the weighted loss (2) on $(x^{new}, y^{tr})$.

For how to select the hyperparameters involved in our methods, please refer to the supplementary material or the approach used for kernel-based conditional independence test (Zhang et al., 2011). The MATLAB source code is available at http://people.tuebingen.mpg.de/kzhang/Code-TarS.zip.

6. Simulation

We use simulations to study the performance of the proposed approach for TarS and LS-GeTarS in four scenarios. They are (a) a nonlinear regression problem under TarS, (b) a classification problem under TarS, (c) a classification problem approximately following LS-GeTarS, and (d) a classification problem under non-LS-GeTarS with slight changes in the conditionals. See Fig. 5 (left) for the training and test points generated...
in one random replication. The training and test sets consist of 500 and 400 data points, respectively.

We compare our approaches to correction for TarS (Section 3) and for LS-GeTarS (Section 5) with the baseline (unweighted) least squares KRR or SVM, the importance weighting approach to correction for covariate shift (CovS) proposed in Huang et al. (2007); Gretton et al. (2008), as well as two “oracle” approaches: one uses the theoretical values of $\beta^*(y) = P^c_{Y} / P^f_{Y}$, and the other trains the learning machine directly on the test set. Note that the result learned on the test set certainly has the best performance, but in practice it cannot be applied; it is given to show the limit of the performance that any domain-adaptation approach can achieve. Since in the considered classification problems $X$ is low-dimensional, it is possible to apply the EM algorithm proposed by Chan & Ng (2005) to estimate $P^c_{Y}$, so it is also included for comparison. We repeated the simulations for 100 times.

Fig. 5 (right) shows the boxplot of the performances of all approaches, measured by the mean square error (MSE) or classification error on the test set; for illustrative purposes, the left panels show the data points generated in one replication as well as the regression lines or decision boundaries learned by selected approaches. Under TarS, (a, b), and non-LS-GeTarS with slightly changing conditionals, (d), compared to the baseline unweighted method, clearly our approaches for TarS and LS-GeTarS improve the performance significantly. For regression under TarS, the estimated $\beta$ values are very close to the theoretical ones, as seen from the lower-right corner of Fig. 5 (a, left). EM achieves a similar performance as TarS, since $P_{X|Y}$ can be modeled well in this simple case. In (c) the conditional $P_{X|Y}$ changes significantly, such that none of the approaches correcting for CovS or TarS helps, but since the change approximately follows LS-GeTarS, our approach for LS-GeTarS greatly improves the classification performance. Compared to the unweighted method, the important reweighting approach for CovS slightly improves the performance in settings (b) and (d), and make it worse in (a) and (c).

7. Real-world Data Sets

We evaluate the performance of the proposed approaches for regression and classification on real data.

7.1. Regression under TarS

We first applied our approach for prediction on suitable data selected from the cause-effect pairs.\(^3\) We

\(^3\)http://webdav.tuebingen.mpg.de/cause-effect/
selected data set No. 68, since 1) the data are non-stationary time series, 2) there is a strong dependence between the two variables so that one can be predicted non-trivially by the other, and 3) the variables are believed to have a direct causal relation, so that the invariance of the conditional distribution of one variable (effect) given the other (cause) is likely to hold approximately. Fig. 6 (top) showing the time series as well as the joint distribution. Here X and Y stand for the number of bytes sent by a computer at the tth minute and the number of open http connections at the same time, respectively. It is natural to have the causal relation \( Y \rightarrow X \). One subsample was always used for training, because on it \( Y \) has large values. The remaining data were divided into four subsets, and each time one of them was used for test and the others included for training.

Fig. 6 (bottom) shows the estimated \( \beta^* \) values on the four test sets; they match \( P^*_Y \) well. Table 2 gives the MSE on the four test sets produced by different approaches. Note that to achieve robustness of the prediction result, we incorporated an exponent \( q \) for \( \beta^* \) as the importance weights, as in correction for CovS with importance re-weighting (Shimodaira, 2000). \( q = 1 \) (i.e., the proposed standard approach) and \( q = 0.5 \) were used. From Table 2 one can see TarS gives the best results on all four test sets.

### 7.2. Remote Sensing Image Classification

Hyperspectral remote sensing images are characterized by a dense sampling of the spectral signature of different land-cover types. We used a benchmark data set in the literature which consists of data acquired by the Hyperion sensor of the Earth Observing 1 (EO-1) satellite in an area of the Okavango Delta, Botswana, with 145 features; for details of this data set, see (Ham et al., 2005). The labeled reference samples were collected on two different and spatially disjoint areas (Area 1 and Area 2), thus representing possible spatial variabilities of the spectral signatures of classes. The samples taken on each area were partitioned into a training set \( TR \) and a test set \( TS \) by random sampling. The numbers of labeled reference samples for each set and class are reported in Table 6. \( TR_1, TS_1, TR_2, \) and \( TS_2 \) have sample sizes 1242, 1252, 2621, and 627, respectively. One would expect that not only the prior probabilities of the classes \( Y \), \( P_Y \), but also \( P_{X|Y} \) would change across the two domains, due to physical factors related to ground (e.g., different soil moisture or composition), vegetation, and atmospheric conditions. Our target is to do domain adaptation from \( TR_1 \) to \( TS_2 \) and from \( TR_2 \) to \( TS_1 \).

After estimating the weights and/or transformed training data (with \( \lambda_{LS} = 10^{-4} \)), we applied the multi-class classifier with a RBF kernel on the weighted or transformed data. Hyperparameters were selected by cross-validation. Table 4 shows the overall classification error (i.e., the fraction of misclassified points) obtained by different approaches for each domain adaptation problem. We can see that in this experiment, correction for target shift does not significantly improve the performance; in fact, the estimated \( \beta \) values...
for most classes are rather close to one. However, correction for conditional shift with LS-GeTarS substantially reduces the overall classification error in both cases.

8. Conclusion and Discussions

We have considered domain adaptation where both the distribution of the covariate and the conditional distribution of the target given the covariate change across domains. From the causal point of view, we assume the target causes the covariate, such that the change in the data distribution can be modeled easily. In particular, we studied three situations, target shift, conditional shift, and generalized target shift which combines the above two situations. We presented practical approaches to handle them based on the kernel mean embedding of conditional and marginal distributions. Simulations were conducted to verify our theoretical claims, and experimental results on diverse real-world problems showed that (generalized) target shift often happens in domain adaptation, and that the proposed approaches could substantially improve the classification or regression performance.

References

Supplement to “Domain Adaptation under Target and Conditional Shift”

This supplementary material provides the proofs and some details which are omitted in the submitted paper. The equation numbers in this material are consistent with those in the paper.

S1. Classification and Regression Machines Used in This Paper

In this paper we consider both the classification and regression problems. For the former problem, we adopt the support vector classification, and for the latter we use the penalized kernel ridge regression. All parameters in the learning machines (e.g., the kernel width and regularization parameter) are selected by cross-validation.

Reweighted support vector classification: Support vector classifiers can be extended to incorporate non-uniform importance weights of the training instances. Associated with each training instance is the importance weight \( \beta^* (y_i) \gamma^*(x_i, y_i) \), which can be incorporated into (1) via the following minimization problem:

\[
\begin{align*}
\text{minimize} & \quad \frac{1}{2} \| \theta \|^2 + C \sum_{i=1}^{n} \beta^*(y_i) \gamma^*(x_i, y_i) \xi_i \\
\text{subject to} & \quad y_i (\langle \theta, \phi(x_i) \rangle + b) \geq 1 - \xi_i, \xi_i \geq 0
\end{align*}
\]

where \( \phi(x) \) is a feature map from \( \mathcal{X} \) to a feature space \( \mathcal{F} \). The dual of (13) is

\[
\begin{align*}
\text{minimize} & \quad \frac{1}{2} \sum_{i=1}^{n} \sum_{j=1}^{n} \alpha_i \alpha_j k(x_i, x_j) - \sum_{i=1}^{n} \alpha_i \\
\text{subject to} & \quad 0 \leq \alpha_i \leq \beta^*(y_i) \gamma^*(x_i, y_i) C, \\
& \quad \sum_{i=1}^{n} \alpha_i y_i = 0
\end{align*}
\]

Here \( k(x, x') \triangleq \langle \phi(x), \phi(x') \rangle_\mathcal{F} \) denotes the inner product between the feature maps. We have modified the LIBSVM implementation\(^4\) for reweighted instances.

Reweighted kernel ridge regression (KRR): The original kernel ridge regression (Saunders et al., 1998) represents the vector of fitted target values as \( \mathbf{f} = Kc \), where \( K \) is the kernel matrix of \( \mathbf{x}^\mathcal{X} \), and find the estimate of \( c \) by minimizing \( (\mathbf{y}^\mathcal{Y} - Kc)^\top \cdot \text{diag} \{ \beta^*(\mathbf{y}^\mathcal{Y}) \circ \gamma^*(\mathbf{x}^\mathcal{X}, \mathbf{y}^\mathcal{Y}) \} \cdot (\mathbf{y}^\mathcal{Y} - Kc) + \lambda_c c^\top Kc \). The estimate is \( \hat{c} = (K + \lambda_c \text{diag}^{-1} \{ \beta^*(\mathbf{y}^\mathcal{Y}) \circ \gamma^*(\mathbf{x}^\mathcal{X}, \mathbf{y}^\mathcal{Y}) \})^{-1} \mathbf{y}^\mathcal{Y} \) and hence, the fitted values are \( \hat{\mathbf{f}} = K \hat{c} = K(K + \lambda_c \text{diag}^{-1} \{ \beta^*(\mathbf{y}^\mathcal{Y}) \circ \gamma^*(\mathbf{x}^\mathcal{X}, \mathbf{y}^\mathcal{Y}) \})^{-1} \mathbf{y}^\mathcal{Y} \).

S2. Proof of Theorem 1 in Sec. 3

Proof 8.1 In (4), \( \mathcal{U}[P_{X|Y}^\mathcal{S}] \) is a linear operator, \( \mathbb{E}_{Y \sim P_{Y}^\mathcal{S}}[\beta(y) \phi(y)] \) is linear in \( \beta \). Further note that the constraints are convex. We can see that the optimization problem (4) is convex in \( \beta \).

According to assumption \( A^\mathcal{S}_{i=2} \), we have \( \mu[P_{X}^\mathcal{S}] = \mathcal{U}[P_{X|Y}^\mathcal{S}] \mu[P_{Y}^\mathcal{S}] \), and the function in (4) reduces to

\[
\| \mathcal{U}[P_{X|Y}^\mathcal{S}] \cdot \{ \mathbb{E}_{Y \sim P_{Y}^\mathcal{S}}[\beta(y) \phi(y)] - \mu[P_{Y}^\mathcal{S}] \} \|.
\]

It achieves zero, which is clearly a minimum, when \( \mathbb{E}_{Y \sim P_{Y}^\mathcal{S}}[\beta(y) \phi(y)] = \mu[P_{Y}^\mathcal{S}] \). It is equivalent to \( \beta(y)P_{X}^\mathcal{S}(y) = P_{Y}^\mathcal{S}(y) \), since the kernel \( k \) is characteristic. Moreover, combining assumptions \( A^\mathcal{S}_{i=1} \) and \( A^\mathcal{S}_{i=2} \) implies that there is no other solution of \( \beta(y) \) to (4).

S3. Proof of Theorem 2 in Sec. 4

Proof 8.2 This theorem is a special case of Theorem 3: in Theorem 3, setting \( P_{Y}^\mathcal{S} = P_{X}^\mathcal{S} = P_{Y}^\mathcal{C} \) gives this theorem.

S4. Derivatives used in Sec. 4.2

The gradient of \( J_{\mathcal{S}} \) w.r.t. \( \mathbf{K} \) and \( \tilde{\mathbf{K}} \) is

\[
\begin{align*}
\frac{\partial J_{\mathcal{S}}}{\partial \mathbf{K}} &= \frac{1}{m^2} (L + \lambda I)^{-1} \mathbf{L} \mathbf{1}_m \cdot \mathbf{1}^\top_m (L + \lambda I)^{-1}, \\
\frac{\partial J_{\mathcal{S}}}{\partial \tilde{\mathbf{K}}} &= -\frac{2}{mn} \mathbf{1}^\top_m \mathbf{L} (L + \lambda I)^{-1}.
\end{align*}
\]

Using the chain rule, we further have the gradient of \( J_{\mathcal{S}} \) w.r.t. the entries of \( \mathbf{G} \) and \( \mathbf{H} \):

\[\text{http://www.csie.ntu.edu.tw/~cjlin/libsvm/}\]
Theorem 3, we have

The derivative of \( \sum \) w.r.t \( \beta \)

\[
\frac{\partial J^{ConS}}{\partial G_{pq}} = \text{Tr} \left[ \left( \frac{\partial J^{ConS}}{\partial K} \right)^\top \cdot (D_{pq} \odot \tilde{K}) \right] - \text{Tr} \left[ \left( \frac{\partial J^{ConS}}{\partial K^c} \right)^\top \cdot (E_{pq} \odot \tilde{K}^c) \right],
\]

where

\[
[D_{pq}]_{ij} = -\frac{1}{l^2} (x_{ij}^{\text{new}} - x_{ij}^{\text{old}})(x_{jq}^{\text{old}} y_{jp} - x_{jq}^{\text{old}} R_{jp}),
\]

\[
[E_{pq}]_{ij} = -\frac{1}{l^2} x_{jq}^{\text{new}} y_{jp} (x_{ij}^{\text{new}} - x_{ij}^{\text{old}}),
\]

\[
[\tilde{D}_{pq}]_{ij} = -\frac{1}{l^2} (x_{ij}^{\text{new}} - x_{ij}^{\text{old}}) (R_{jp} - R_{ip}),
\]

\[
[\tilde{E}_{pq}]_{ij} = -\frac{1}{l^2} R_{jp} (x_{ij}^{\text{new}} - x_{ij}^{\text{old}}),
\]

The derivative of \( J^{reg} \) w.r.t. \( G \) and \( H \) is

\[
\frac{\partial J^{reg}}{\partial G} = \frac{2\lambda_{LS}}{m} R^\top (W - 1_m 1^\top), \quad \text{and} \quad \frac{\partial J^{reg}}{\partial H} = \frac{2\lambda_{LS}}{m} R^\top B.
\]

**S5. Proof of Theorem 3 in Sec. 5**

Combining assumption \( A^{ConS} \), i.e., \( P_{X}^{te} = \sum_i P_i^{te}(y_i) P_{X|Y}^{(w_i, b_i)}(x|y_i) \), and the condition in Theorem 3, we have

\[
\sum_i P_i^{te}(y_i) P_{X|Y}^{(w_i, b_i)}(x|y_i) = \sum_i P_i^{new}(y_i) P_{X|Y}^{(w_i, b_i)}(x|y_i)
\]

\[
= \sum_i \left[ P_i^{te}(y_i) P_{X|Y}^{(w_i, b_i)}(x|y_i) - P_i^{new}(y_i) P_{X|Y}^{(w_i, b_i)}(x|y_i) \right] = 0.
\]

Because of assumption \( A_2^{ConS} \), we know that \( \forall i \)

\[
P_i^{te}(y_i) P_{X|Y}^{(w_i, b_i)}(x|y_i) - P_i^{new}(y_i) P_{X|Y}^{(w_i, b_i)}(x|y_i) = 0.
\]

Taking the integral of the above equation gives

\[
P_{Y|X}^{new}(y_i) = P_{Y|X}^{te}(y_i).
\]

This further implies

\[
P_{X|Y}^{(w_i, b_i)}(x|y_i) = P_{X|Y}^{(w_i, b_i)}(x|y_i) = P_{X|Y}^{te}(x|y_i).
\]

**S6. Algorithm for LS-GeTarS in Sec. 5**

We iteratively alternate between the QP to minimize (11) w.r.t \( \beta \) and the SCG optimization procedure w.r.t. \{\( W, B \)\}. Algorithm 1 summarizes this procedure for clarity. For details of the two optimization sub-procedures, see Sections 3 and 4, respectively. After estimating the parameters, we train the learning machine by minimizing the weighted loss (2) on \((x^{\text{new}}, y^{\text{tr}})\).

**S7. Determination of Hyperparameters**

As discussed in Sec. 2, all hyperparameters in the subsequent learning machines reweighted SVM and KRR are selected by importance weighted cross-validation (Sugiyama et al., 2007). In addition, there are three types of hyperparameters. One is the kernel width of \( X \) to construct the kernel matrix \( K \). In our experiments we normalize all variables in \( X \) to unit variance, and use some empirical values for those kernel widths: they are set to \( 0.8\sqrt{d} \) if the sample size \( m \leq 200 \), to \( 0.3\sqrt{d} \) if \( m > 200 \), or to \( 0.5\sqrt{d} \) otherwise, where \( d \) is the dimensionality of \( X \). This simple setting always works well in all our experiments; for a more principled strategy, one might refer to Gretton et al. (2012).

The second type of hyperparameters is involved in the parameterization of \( \beta \) for regression under TarS (the kernel width for \( L_\beta \) and regularization parameter \( \lambda_\beta \)) and \( \lambda_{LS} \) for LS-GeTarS in (12). We set these parameters by cross-validation. (On some large data sets we simply set \( \lambda_{LS} \) to 0.001 to save computational load.) Although the objective functions (Eq. 5 for TarS, and Eq. 11 for LS-GeTarS) is the sum of squared errors, the corresponding problems are considered unsupervised, or in particular, as density estimation problems, rather than supervised. We treat \( P_{X}^{new} \) as the distribution given by the model, and \( x^{te} \) as the corresponding observed data points. They are different from the classical density estimation problem in that here we use the maximum mean discrepancy between \( P_{X}^{new} \) and \( P_{X}^{y} \) as the loss function. We divide \( x^{te} \) into five equal size subsamples, use four of them to estimate \( \beta \) or
W and B, and the remaining one for testing. Finally we find the values of these hyperparameters that give the smallest cross-validated loss, which is (5) for regression under TarS or (11) for LS-GeTarS. The last type of hyperparameters, including hyperparameters in L and the regularization parameter λ, are learned by the extension of Gaussian process regression in the multi-output case (Zhang et al., 2011).

S8. Details of Simulation Settings in Sec. 6

The four simulation settings are

(a) a nonlinear regression problem \( X = Y + 3 \tanh(Y) + E \), where \( E \sim \mathcal{N}(0, 1.5^2) \); \( Y^{tr} \sim \mathcal{N}(0, 2^2) \), and \( Y^{te} \sim 0.8N(1, 1) + 0.2N(0, 2, 0.5^2) \),

(b) a classification problem under TarS, where

\[
X|Y=-1 \sim \mathcal{N}(0, [0.21 0.09 0.21]), \quad X|Y=1 \sim \mathcal{N}(1, [0.31 -0.06 0.31]),
\]

\[
P_Y^t(y = -1) = 0.6, \quad \text{and} \quad P_Y^{te}(y = -1) = 0.2,
\]

(c) a classification problem approximately following location-scale GeTarS, where

\[
X'|Y^{tr}=-1 \sim \mathcal{N}(0, [0.24 0.22 0.22]),
\]

\[
X'|Y^{tr}=1 \sim \mathcal{N}(1, [0.16 -0.03 0.16]),
\]

\[
X'|Y^{te}=-1 \sim \mathcal{N}(1, [0.5 0 0.11 0.12]),
\]

\[
X'|Y^{te}=1 \sim \mathcal{N}(2, [0.27 -0.04 0.27]),
\]

\[
P_Y^t(y = -1) = 0.6, \quad \text{and} \quad P_Y^{te}(y = -1) = 0.3, \quad \text{and}
\]

(d) a classification problem with non-location-scale GeTarS with slight change in the conditional, where

\[
X'|Y^{tr}=-1 \sim \mathcal{N}(0, [0.16 0 0.16]),
\]

\[
X'|Y^{tr}=1 \sim \mathcal{N}(1, [0.23 0 0.23]),
\]

\[
X'|Y^{te}=-1 \sim \mathcal{N}(0.1, [0.10 -0.03 0.10]),
\]

\[
X'|Y^{te}=1 \sim \mathcal{N}(0.8, [0.11 0.05 0.05 0.11]),
\]

\[
P_Y^t(y = -1) = 0.6, \quad \text{and} \quad P_Y^{te}(y = -1) = 0.2.
\]

S9. Results on Pseudo Real-world Data Sets in Sec. 7

Table 5 reports the results on pseudo real-world data sets. In these experiments, we split each data set into training set and test set. The percentage of training samples ranges from 60% to 80%. Then, we perform the biased sampling on the training data to obtain the shifted training set. Letting \( P(s = 1|y) \) be the probability of sample x being selected given that its true output value is y, we consider the following two biased sampling schemes for selecting training data: (1) Weighted Label uses \( P(s = 1|y) = \exp(a + by)/(1 + \exp(a + by)) \) denoted by label\((a,b)\), and (2) PCA. In this case, we generate biased sampling schemes over the features. Firstly, a kernel PCA is performed on the data. We select the first principal component and the corresponding projection values. The biased sampling scheme is then a normal distribution with mean \( m + (\bar{m} - m)/a \) and variance \( (\bar{m} - m)/b \) where \( m \) and \( \bar{m} \) are the minimum value of the projection and the mean of the projection, respectively. We denote this sampling scheme by PCA\((a,b,\sigma)\), where \( \sigma \) is the bandwidth of the Gaussian RBF kernel. In summary, the LS-GeTarS outperforms Unweight, CovS, and TarS on 5 out of 6 data sets for classification problem. The TarS outperforms all other approaches on one of these data sets. For regression problem, TarS outperforms the Unweight and Covs on 7 out of 12 data sets.

S10. Details of Remote Sensing Image Classification

Hyperspectral remote sensing images are characterized by a dense sampling of the spectral signature of different land-cover types. We used a benchmark data set in the literature which consists of data acquired by the Hyperion sensor of the Earth Observing 1 (EO-1) satellite in an area of the Okavango Delta, Botswana, with 145 features; for details of this data set, see (Ham et al., 2005). The labeled reference samples were collected on two different and spatially disjoint areas (Area 1 and Area 2), thus representing possible spatial variabilities of the spectral signatures of classes. The samples taken on each area were partitioned into a training set \( TR \) and a test set \( TS \) by random sampling. The numbers of labeled reference samples for each set and class are reported in Table 6. \( TR_1 \), \( TS_1 \), \( TR_2 \), and \( TS_2 \) have sample sizes 1242, 1252, 2621, and 627, respectively. One would expect that not only the prior probabilities of the classes \( Y \), but also the conditional distribution of \( X \) given \( Y \) would change across them, due to physical factors related to ground (e.g., different soil moisture or composition), vegetation, and atmospheric conditions. Our target is to do domain adaptation from \( TR_1 \) to \( TS_2 \) and from \( TR_2 \) to \( TS_1 \).
Table 5. The results of different distribution shift correction schemes. The results are averaged over 10 trials for regression problems (marked *) and 30 trials for classification problems. We report the normalized mean squared error (NMSE) for regression problem and test error for classification problem.

After estimating the weights and/or the transformed training points, we applied the multi-class classifier with a RBF kernel, provided by LIBSVM, on the weighted or transformed data. Each time, the kernel size and parameter $C$ were chosen by five-fold cross-validation over the sets $\{2^{5/2}, 2^{3/2}, 2^{1/2}, 2^{-1/2}, 2^{-3/2}, 2^{-5/2}\} \times \sqrt{d}$ and $\{2^6, 2^8, 2^{10}, 2^{12}, 2^{14}, 2^{16}, 2^{18}\}$, respectively. (We found that the selected values always belonged to the interior of the sets.)

</table>
see Fig. 7. One can see that for both domain adaptation problems, LS-GeTarS improves the classification accuracy on classes 11, 9, and 3. It also leads to significant improvement on class 13 for the problem $TR_1 \rightarrow TS_2$, and on class 2 for $TR_1 \rightarrow TS_2$. Note that this is a multi-class classification problem and we aim to improve the overall classification accuracy; to achieve that, the accuracy on some particular classes, such as classes 10 and 6, could be worse. Fig. 8 plots some of the estimated scale transformation coefficients $w(y^{tr})$ and location transformations $b(y^{tr})$ that are significant (i.e., $w(y^{tr})$ is significantly different from one, and $b(y^{tr})$ different from zero). One can see that roughly speaking, the transformation learned for the domain adaptation problem $TR_2 \rightarrow TS_1$ is the inverse of that for the problem $TR_1 \rightarrow TS_1$.

S11. Experiment on TRECVID Concept Detection

In this experiment, we consider automatic assignment of semantic tags to video segments, which can be a fundamental technology for content-based video search (Smeaton et al., 2009). For each semantic concept, classifiers can be obtained from annotated training data (source domain) and used to determine the presence of the concept for each segment in test data.

![Estimated location transformation for selected classes for domain adaptation $TR_2 \rightarrow TS_1$.](image6)

Figure 8. Estimated scale transformation coefficient $w(y^{tr})$ and location transformation $b(y^{tr})$ for selected classes by correction for LS-GeTarS. (a, b) For domain adaptation from $TR_1$ to $TS_2$. (c, d) For domain adaptation from $TR_2$ to $TS_1$. 
We consider the 39 semantic concepts from the LSCOM-lite lexicon (Naphade et al., 2005), with annotation on the TRECVID 2005 data set. The data set contains 61,901 segmented video shots from 108 hours of television programmes from six different broadcast channels, including three English channels (CNN, MSNBC and NBC), two Chinese channels (CCTV and NTDTV) and one Arabic channel (LBC). For each shot, 346 low-level features were extracted from its keyframe (Yang et al., 2007), including Grid Color Moment (225 dim.), Gabor Texture (48 dim.), and Edge Detection Histogram (73 dim.). We split the data set into a source domain that consists of video shots from the English and Chinese channels, and a target domain that contains shots from the Arabic channel.

We apply asymmetric bagging to handle the scarcity of positive training instances (Tao et al., 2006). For each concept, five SVM classifiers were trained using up to 1000 positive training instances and the randomly sampled same amount of negative instances. The overall rank list on the test data was obtained from the average classification confidence. We used the default parameters for training the SVM classifiers, as suggested by Tao et al. (2006)

The average precision of all concepts is shown in Fig. 9. Overall, TarS achieved a Mean Average Precision (MAP) of 0.2345 across all concepts, and outperformed the baseline method (MAP: 0.2272). TarS achieved substantial improvements on concepts such as Snow, Vegetation, and Flag-US, where $P_Y$ varies significantly. LS-GeTarS further improved the performance and achieved an MAP of 0.2358. As shown in Fig. 9, LS-GeTarS worked particularly well for the concept Snow, where considerable conditional shift is expected. Note that our methods should be distinguished from previous work by Duan et al. (2009), as we do not use any annotation from the target domain.
